ABSTRACT

PURPOSE: Often, the controversial diagnosis of chronic Lyme disease is given to patients with prolonged, medically unexplained physical symptoms. Many such patients also are treated for chronic coinfections with Babesia, Anaplasma, or Bartonella in the absence of typical presentations, objective clinical findings, or laboratory confirmation of active infection. We have undertaken a systematic review of the literature to evaluate several aspects of this practice.

METHODS: Five systematic literature searches were performed using Boolean operators and the PubMed search engine.

RESULTS: The literature searches did not demonstrate convincing evidence of: 1) chronic anaplasmosis infection; 2) treatment-responsive symptomatic chronic babesiosis in immunocompetent persons in the absence of fever, laboratory abnormalities, and detectable parasitemia; 3) either geographically widespread or treatment-responsive symptomatic chronic infection with Babesia duncani in the absence of fever, laboratory abnormalities, and detectable parasitemia; 4) tick-borne transmission of Bartonella species; or 5) simultaneous Lyme disease and Bartonella infection.

CONCLUSIONS: The medical literature does not support the diagnosis of chronic, atypical tick-borne coinfections in patients with chronic, nonspecific illnesses.

KEYWORDS: Anaplasma; Babesia; Bartonella; Borrelia burgdorferi; Coinfection; Lyme disease

Lyme disease is the most commonly reported vector-borne infection in the US with over 30,000 confirmed or probable cases in 2011. Lyme disease is caused by infection with the spirochete Borrelia burgdorferi and transmitted by Ixodes spp. ticks. While many aspects of Lyme disease are well accepted by the mainstream medical community, considerable controversy surrounds “chronic Lyme disease,” an ill-defined diagnosis that some clinicians give to patients with alternative diagnoses or medically unexplained symptom complexes. In many instances these patients also are diagnosed with chronic coinfection with Anaplasma, Babesia, or Bartonella. In the context of chronic Lyme disease, these pathogens often are diagnosed in the absence of typical presentations or objective clinical findings, and without laboratory confirmation.

In this systematic review we address several major questions relevant to the diagnosis of coinfections in patients with a diagnosis of chronic Lyme disease. These questions are the following:

1) Is there evidence of persistent human granulocytic anaplasmosis (HGA)?
2) How is relapsing or persisting babesiosis identified and diagnosed?
3) Has chronic Babesia duncani infection been described?
4) Is there convincing evidence for tick-borne human Bartonella infection?
5) Is there convincing evidence for simultaneous Lyme disease and Bartonella infection?

METHODS
In order to identify relevant articles, we performed the following Boolean searches of the indexed medical literature using the PubMed search engine.

Search 1
For evidence of chronic human anaplasmosis:

(Anaplasma OR anaplasmosis OR ehrlichia OR ehrlichiosis OR phagocytophilum) AND (chronic OR persistent OR recurrent OR relapse)

Search 2
To characterize chronic or relapsing babesiosis:

(Babesia OR babesiosis) AND (chronic OR persistent OR recurrent OR relapse)

Search 3
For the role of Babesia duncani in human disease:

babesia AND (duncani OR WA1)

Search 4
For tick-borne Bartonella infection:

(tick OR Ixodes) AND (Bartonella OR bartonellosis)

Search 5
For simultaneous Lyme disease and bartonellosis:

(Lyme OR borrelia OR borreliosis) AND (Bartonella OR bartonellosis)

Case reports, case series, and primary scientific studies were selected from among the search results. Review articles, correspondence, and editorials were excluded. We limited our search to studies with human subjects. This was done by manually reviewing the articles and excluding those in which the subjects were nonhuman (rather than adding a search function limit to the PubMed query). Because Anaplasma phagocytophilum was formerly categorized as Ehrlichia, we included Ehrlichia and ehrlichiosis in the search terms for this query.

RESULTS

Search 1: Persistent, Chronic, or Recurrent Human Granulocytic Anaplasmosis

This search yielded 252 articles. The vast majority of scientific articles yielded by these search terms were animal studies. Many addressed microorganisms other than A. phagocytophilum. Ultimately, only 2 studies were appropriate for further review based on our inclusion criteria. In the first, 2 febrile asplenic patients were diagnosed with HGA based on blood smear examination. One developed neurologic symptoms including left-sided weakness, left hemi-neglect, and delirium within 12 days of an admission in which HGA had been diagnosed and treated. His blood smear examination was negative at this second visit and he was apparently afebrile, so recurrent HGA was not definitively established; nonetheless, he received doxycycline and promptly improved. The second asplenic patient was treated uneventfully with 10 days of doxycycline and suffered no relapse. A second study reported HGA in 3 recipients of pancreas transplantation. While all of the patients had overall complicated medical courses, none had evidence of recurrent or chronic HGA. This study was reported from Kentucky, a state where HGA is not known to be endemic.

Search 2: Persistent or Relapsing Human Babesiosis

This search yielded 200 articles. Of these, 31 were retrieved for further analysis after screening as described in the Methods section. A large number of these studies documented relapsing or persistent babesiosis or babesiosis whose diagnosis was delayed; complicated disease predominately affected asplenic or otherwise immunocompromised patients. Fever, laboratory abnormalities such as anemia, and direct evidence of parasitemia such as a positive blood film examination or polymerase chain reaction (PCR) assay were nearly universal among the reported patients. The literature search did not yield evidence of cryptic babesiosis resulting in a less overt syndrome. A study of patients with chronic fatigue syndrome found seroreactivity to Babesia microti in 2 controls but not in any of the study subjects with chronic fatigue. A case series of 3 patients attributed panic attacks to infection with multiple tick-borne pathogens including babesiosis. In 2 of the 3 cases, presumptive of babesiosis was based solely on antibody titers — an immunoglobulin M (IgM) titer of 1:80 in one case and a “low positive” titer in the other. A third patient in this series reportedly had B. microti DNA detected by PCR. Details of the PCR reaction were not provided, there was no report of a blood film examination, and no report of

CLINICAL SIGNIFICANCE

- There is no evidence to support a diagnosis of chronic anaplasmosis in humans.
- Persistent or relapsing babesiosis is accompanied by fever and demonstrable parasitemia.
- There is little evidence to support tick-borne Bartonella infection or Bartonella-Lyme coinfection.
laboratory testing to evaluate hemolysis; the article reports that the patient’s panic attacks were eliminated after 9 months of “increasingly aggressive antimicrobial therapy for tick-borne diseases.” None of the antibiotics listed in the article has known efficacy for human babesiosis.

Search 3: Babesia duncanii Infection
This search yielded 26 articles. Of these, we identified 13 case reports, case series, or human studies for further review. The remainder was comprised of review material or animal studies. Two instances were reports of a Babesia divergens-like pathogen, and infection with B. duncanii was excluded.

Infection with B. duncanii, formerly designated WA1, has been described in 8 patients in the medical literature. A total of 200 articles was identified, the great majority of them reporting the detection of Bartonella within ticks. Nine articles were reviewed further for direct evidence of human Bartonella infection transmitted by a tick bite, or the vector competence of ticks to transmit Bartonella spp. to a host. The most direct evidence of tick-borne human bartonellosis comes from a study of 3 patients from southern France investigating the “scalp eschar and neck lymphadenopathy after tick bite” syndrome. The eschars from 2 of these patients were positive by PCR for B. henselae. Our search did not yield other articles demonstrating tick transmission of Bartonella to humans. Three studies have demonstrated transmission of Bartonella spp. by ticks using artificial feeding systems and murine transmission models. One study demonstrated that the brown dog tick, Rhipicephalus sanguineus, could become infected with B. vinsonii subsp. berkhoffii when feeding using a capillary tube system. A second study found that I. ricinus ticks could acquire B. henselae after feeding on infected blood using a membrane feeding system. Neither of these studies demonstrated transmission of the organism from the tick to a mammalian host. The only study to do so found that B. birtlesii could be transmitted to mice by I. ricinus. This study has not been corroborated by evidence that transmission occurs in nature. No study has yet investigated transmission of B. henselae by I. scapularis.

Search 4: Evidence of Tick-borne Human Bartonella Infection
A total of 200 articles was identified, the great majority of them reporting the detection of Bartonella within ticks. Nine articles were reviewed further for direct evidence of human Bartonella infection transmitted by a tick bite, or the vector competence of ticks to transmit Bartonella spp. to a host. The most direct evidence of tick-borne human bartonellosis comes from a study of 3 patients from southern France investigating the “scalp eschar and neck lymphadenopathy after tick bite” syndrome. The eschars from 2 of these patients were positive by PCR for B. henselae. These patients, however, did not have an identified tick bite, and had other risk factors for Bartonella infection (including cat exposure). A third patient had an eschar that was negative by PCR for B. henselae. He did, however, provide an ornate sheep tick, Dermacentor marginatus, that was retrieved from the site of the eschar; this tick was positive for B. henselae. Our search did not yield other articles demonstrating tick transmission of Bartonella to humans. Three studies have demonstrated transmission of Bartonella spp. by ticks using artificial feeding systems and murine transmission models. One study demonstrated that the brown dog tick, Rhipicephalus sanguineus, could become infected with B. vinsonii subsp. berkhoffii when feeding using a capillary tube system. A second study found that I. ricinus ticks could acquire B. henselae after feeding on infected blood using a membrane feeding system. Neither of these studies demonstrated transmission of the organism from the tick to a mammalian host. The only study to do so found that B. birtlesii could be transmitted to mice by I. ricinus. This study has not been corroborated by evidence that transmission occurs in nature. No study has yet investigated transmission of B. henselae by I. scapularis.

Search 5: Evidence of Simultaneous Lyme Disease and Bartonella spp. Infection
This search yielded 155 articles, of which 8 were appropriate for further review based on the criteria described in the Methods section. Three of these publications presented patients with putative Bartonella/Lyme disease coinfections. One patient had several months of nonspecific symptoms, then sudden vision loss that was attributed to neuroretinitis. Titters were strongly positive to B. henselae (>=1:1024). The patient had detectable peripheral and cerebrospinal fluid IgM antibodies to B. burgdorferi, but had a positive B. burgdorferi IgG by established interpretive criteria. The second publication reported 4 symptomatic patients in whom DNA from both B. henselae and B. burgdorferi were found in the cerebrospinal fluid. Only one of these subjects was seropositive to B. burgdorferi. Very little clinical information was given about these patients, including whether there was cerebrospinal fluid evidence of meningitis. Amplicons from PCR reactions were not sequenced. Finally, a third publication reported testing results from 2 patients from Poland with meningitis; no further clinical details were provided in the study. Of these patients, one had B. henselae DNA in the cerebrospinal fluid; this individual was seronegative for antibodies to B. henselae, but had detectable IgG antibodies to B. burgdorferi. A second patient was found to have equivocal levels of antibodies to B. henselae and equivocal levels of IgM antibodies to B. burgdorferi. Serologic evaluation for Lyme disease in this study did not correspond to current recommendations for 2-tier testing.

A number of other studies have suggested that occupationally exposed individuals are frequently seropositive for antibodies to both B. burgdorferi and Bartonella. A serosurvey of at-risk individuals in Lublin, Poland (forestry workers and farmers) found that 8.9% of individuals had antibodies to both Bartonella spp. and B. burgdorferi. A separate study from the Warsaw region found seropositivity to both organisms in 10% of forestry workers. A study of patients with a variety of rheumatic disease manifestations...
from a Lyme disease-hyperendemic region found antibodies to *Bartonella* in 62% of subjects and direct detection of the organism in 41.1%; none of these patients, however, had documentation of Lyme disease. Finally, in an Australian study, 2 patients were described as having evidence of simultaneous *Bartonella* infection and Lyme disease. The clinical syndromes from these patients were not described; their seropositivity to *Bartonella* was an isolated IgM titer of 1:40, and these subjects only had IgM seroreactivity to *B. burgdorferi*.33

**DISCUSSION**

There is no debate in the scientific community that *Ixodes* spp. ticks transmit a number of important human pathogens, and sometimes in combination. In addition to *B. burgdorferi*, the causative agent of Lyme disease, *Ixodes* ticks may transmit *B. microti* and other human *Babesia* species, *A. phagocytophilum*, tick-borne encephalitis virus, Powassan virus, and emerging pathogens such as *Borrelia miyamotoi*. These infections may occur in isolation or in various combinations, and it is well established that coinfections have important clinical, diagnostic, and therapeutic implications. Active infection is characterized by objective clinical findings (eg, fever or laboratory abnormalities). Practitioners who frequently offer the diagnosis of chronic Lyme disease often do not rely on more accepted standards of clinical and laboratory testing. In such circumstances, many patients also receive spurious diagnoses of chronic anaplasmosis, babesiosis, and bartonellosis.

We have performed a systematic review of the medical literature in order to evaluate whether published science supports chronic, cryptic infections with these pathogens. Because of basic biological, clinical, and epidemiologic differences among HGA, babesiosis, and bartonellosis, different search terms were required for each pathogen.

*A. phagocytophilum*, the causative agent of HGA, is a rickettsial organism that produces an acute febrile systemic illness within about 2 weeks of an infectious tick bite. Infection is characterized by fever, constitutional symptoms, and laboratory abnormalities such as leukopenia, thrombocytopenia, and elevated levels of hepatic transaminases. Although HGA is potentially fatal, the infection will be self-limited in survivors regardless of whether they are treated. As HGA is an infection of circulating leukocytes, both blood film examination and PCR of the blood can establish the presence of infection. Our search did not yield any reports of chronic, relapsing, or refractory HGA in humans. Persistent infection in domestic and wild ruminants, and persistent veterinary infections with related microorganisms (eg, *Anaplasma marginale*) cannot be assumed to predict the plausibility of chronic HGA in humans. To date there is no basis upon which to diagnose a human patient with chronic HGA.

Babesiosis is a malaria-like protozoan infection of erythrocytes that is transmitted by *Ixodes* spp. ticks. It may also be acquired from blood transfusions. Several species of *Babesia* are capable of causing human disease; the most important of these are *B. microti* in the Northeastern and Midwestern US and *B. divergens* in Europe. Lyme-Babesia coinfection has been well established and may result in greater disease severity. Clinical babesiosis is nearly always dominated by fever and characteristic laboratory abnormalities, and the infection can be proved by direct visualization of the parasite on blood smear or detection of its DNA by blood PCR.

Relapsing or persistent infection can occur in immunocompromised patients, particularly those with lymphoma who are asplenic and received treatment with rituximab. Persistent babesiosis produces the same clinical and laboratory abnormalities that are seen in acute babesiosis, and patients remain both PCR and blood smear positive. In fact, immunocompromised patients who are at risk of persistent or recurrent babesiosis often have higher parasitemias and generally more severe disease. This is the only group of patients for whom there is evidence that a course of anti-babesia drug therapy that exceeds 10 days duration is beneficial. We found no evidence that active babesiosis, as demonstrated by a positive PCR or blood smear, produces purely subjective complaints (eg, fatigue, pain, cognitive symptoms) that are unaccompanied by fever or by laboratory abnormalities. Asymptomatic blood donors have been the index cases for transfusion-associated babesiosis, so it may be the case that patent infection can actually be subclinical or nonspecific. If PCR-negative patients with purely subjective symptoms due to babesiosis exist, there are no published data on whether antibabesia therapy might be beneficial for them. The current standard of care is to treat only those individuals who can be shown by direct molecular or microscopic testing to have active babesiosis. Seroprevalence to *B. microti* clearly exceeds the incidence of clinically evident infections, suggesting that many individuals experience subclinical and asymptomatic infections. Thus, reliance on serology in the absence of direct demonstration of the organism could lead to erroneously attributing coincident symptoms to active infection.

This is particularly true for *B. duncani*, a pathogen responsible for a small number of human cases in the Pacific Northwest. Like other human babesias, *B. duncani* produces fever and hemolysis. Among the limited case reports there was no evidence of cryptic infection resulting only in subjective complaints. The high rates of background seropositivity to *B. duncani*, including in supposedly nonendemic areas according to one report, raise the question of whether there are cross-reactive antibodies in the population at large. This underscores the importance of directly demonstrating intraerythrocytic infection when pursuing a diagnosis of active babesiosis.

Unlike HGA and babesiosis, which in nature are exclusively transmitted to humans by *Ixodes* spp. ticks, we have found no convincing evidence that this is a natural or even plausible mode of transmission for *Bartonella* spp. Our search yielded no case in which tick-borne bartonellosis was
unequivocally established. Not only is tick-borne human bartonellosis unfounded to date, but there is very little literature to support Lyme disease—Bartonella coinfection at all, regardless of the means of acquisition. Moreover, appropriate seroepidemiologic studies have not even been attempted in Lyme disease patients in the US to evaluate the seroprevalence of B. henselae in such individuals. While several small case series and reports in the literature purport to describe simultaneous Lyme disease and Bartonella infection, in no case did the laboratory corroboration of Lyme disease correspond to established diagnostic standards.

The putative association between ticks, Lyme disease, and B. henselae infection is ultimately derived from 2 problematic sources of data. The first is a limited number of reports of mostly European subjects in whom clinical infection with B. henselae and B. quintana has been temporally associated with a tick bite.47–49 The second source of data is the observation that many tick specimens contain Bartonella DNA when subjected to PCR analysis.30–54 This has been demonstrated primarily in the Eurasian ticks I. ricinus and I. persulcatus, and to a lesser degree, in the North American tick I. scapularis. Nonetheless, it should come as no surprise that ticks would contain Bartonella DNA — ticks feed on a variety of mammalian hosts that may be reservoirs for Bartonella spp. The presence of Bartonella DNA in the tick does not prove that the tick is a competent vector for transmission to a second mammalian host. Vector competence of I. scapularis ticks for B. henselae has never been demonstrated in an animal system.

CONCLUSION

The Ixodes spp. ticks that transmit B. burgdorferi are capable vectors of several human pathogens. In all cases, however, these infections produce defined clinical syndromes that are corroborated by objective clinical and laboratory findings. This is true for well-established Babesia-Lyme and Anaplasma-Lyme coinfections. Treatment and diagnosis of chronic coinfections, however, is clearly not justifiable in the absence of convincing objective evidence that these infections are present and active.
